# **ABOUT JGRP**

**Journal of Geography and Regional Planning (JGRP)** is a peer reviewed open access journal. The journal is published monthly and covers all areas of the subject.

**Journal of Geography and Regional Planning (JGRP)** is an open access journal that publishes high-quality solicited and unsolicited articles, in all areas of Journal of Geography and Regional Planning such as Geomorphology, relationship between types of settlement and economic growth, Global Positioning System etc. All articles published in JGRP are peer-reviewed.

Understanding the factors and processes controlling catchment sediment yield is crucial and fundamental to water resources management and development. This review provides an inventory on land use and sediment yield studies in Ghana and explores their existing link. The review through desktop studies analyzed the discussions and related studies on the impact of land use/cover change on sediment yield. Available literature showed that generally sediment yield is sensitive to land use/cover, however, the evidence of the empirical link between land use/cover and the catchment sediment yield is unclear. Though various land use/cover and sediment yield studies have contributed to the understanding of the variations in catchment erosion rate resulting from land use/cover changes, the results do not show strong influence of cover types on sediment yield. The results relate sediment yield to rainfall, runoff and catchment area without exploring the empirical evidence of land use impact. Thus, empirically, the extent to which sediment yield varies with land use /cover changes still remain unclear. Further research is recommended to ascertain the empirical link between land use/cover change and catchment sediment yield.

Key words: Sediment yield, river basin, land use/cover changes, water resources management.

#### INTRODUCTION

Amongst the issues threatening water security both in quantity and quality in Ghana is the increasing rate of river basin's sediment yield, transport and deposition (Eswaran et al., 2001). Sediment yield is the mass of sediment annually leaving a catchment per unit area (Verstraeten and Poesen, 2001). It is the results of

erosion and deposition processes within a catchment. Sediment yield and transport has been noted for altering the hydrological regimes of river basins (Ayivor and Gordon, 2012). High sediment yield usually comes with elevated soil loss within catchment, which compromises soil productivity affecting water quality and quantity as

well as flood and control fishing, in addition to reducing reservoir lifespan and modifying river channel morphology (Mensah, 2009; Kusimi, 2008b; Peng et al., 2008). Thus, reliable information on the expected sediment yield of river basins is important for water resources management and development (Kusimi et al., 2014; Akrasi, 2011).

The sediment yield of a catchment result from the multiplicative effects of land use, climate, basin's size, geology and topography (Inca, 2009; Morehead et al., 2003; Milliman et al., 1999). The relative importance and sensitivity of these factors in explaining the spatial variation in sediment yield is crucial. Hence, the physical mechanisms responsible for the variation in sediment loads must be explained in order to have proper understanding of the interaction between sediment yield and these related factors responsible for the variability in sediment load. This is fundamental in addressing the hydrological challenges of river basins in order to predict the potential impact of existing practices and trends.

The influence of land use/cover on the sediment yield of a catchment is acknowledged by both land use and sediment researchers. Land use refers to the utilization of land for economic or productive use (IPCC, 2001) whilst land cover refers to the biophysical status of the earth's surface and immediate sub-surface (Campbell, 2002). The status of land use/cover determines the influence of rainfall intensity on erosion rate, transport and deposition (Costa et al., 2003). Therefore, changes in land use patterns automatically determine the variations in the catchment sediment yield. Hence, it is important to understand clearly the relative importance of land use/cover changes in explaining the spatial variation in sediment yield. The available evidence regarding the impact of conversion of land use type to another on the sediment loads of rivers must however, be explored. The aim of this study is to review and provide inventory on land use and sediment yield studies in Ghana and to explore their empirical relationship. This will help enhance the understanding of the link between land use, erosion and sediment yield in Ghana, which is fundamental to the development of sustainable land use alternatives as an integral component of river basin and water resources management.

#### LAND USE AND LAND COVER STUDIES IN GHANA

Land use and land cover studies are important in water resources development and management as it directly affect the hydrological processes of river basin's (Costa et al., 2003; Fohrer, 2001). Accurate knowledge of existing land use and cover practices and trends represent the foundation for water resources management (Kelarestaghi and Jeloudar, 2011).

Land use has been defined by IPCC (2001) and IGBP/IHDP (1993) as the utilization of land for economic or productive use. Hence, land use is based on function,

the purpose for which the land is being used or the entire range of direct management activities that affect the nature of the land (Aduah et al., 2015; Campbell, 2002) such as agricultural, forestry, industry, as others related. On the other hand, land cover refers to the biophysical status of the earth's surface and immediate sub-surface (Briassoulis, 2006; FAO, 1997) including vegetation, human constructions, water, etc. It must be emphasized that land cover is the visual result of land use at a certain moment in time whilst land use reflects the degree of human activities directly related to land and making use of its resources.

While the earth's land mass remains essentially static with time and space, human demands have changed and increased, impacting heavily on the land as well as its flora and fauna composition in various ways (Ndulue et al., 2015). Consequently, the land use and cover characteristics are being changed from time to time. The conversion or alteration of the natural landscape or changes in structure and function (quantitative) and changes in the areal extent (qualitative) of a given type of land use or cover refers to land use and land cover (LULC) change (Seto et al., 2002; Briassoulis, 2006). Thus, land cover change has a unique signature on the topography and soil distribution, that gives rise to changes in natural resource.

The first land use map of Ghana using remote sensing was completed in 1998, at a scale of 1: 250,000 under the Ghana Environmental Resource Management Programme (GERMP) (Amatekpor, 1999). Since then there have been several applications of remote sensing in land use studies (Table 1). Some are published in refereed journals whilst others are unpublished masters' and PhD theses from universities across the globe. Generally, land use and land cover studies have been focused on land use/cover change assessment and prediction (Basommi et al., 2015), land use and climate (Dale, 1997), land use and water resources (Ayivor and Gordon, 2012), land use and soil erosion and sediment (Kavian et al., 2014), drivers of land use change (Braimoh and Vlek, 2005).

Over the year's various land use and land cover studies in Ghana, using different methods and techniques have shown obvious occurrence of land use and land cover changes. Results of studies within the tropical forest zones shows consistent decline of forest lands (Forkuo and Adubofour, 2012) whilst those within the savanna belt shows conversion from savanna lands to urban and farm lands (Adusei, 2014). For example, the review of historical document by FAO (2015) showed that between 1975 and 2000, agricultural lands expanded from 13 to 28% and increased rapidly to 32% of Ghana's total land area in 2013. The changing status of the forest area towards farmlands, urban lands and mining areas has been reported in several land use and land cover studies carried out in different areas for different periods (Table 1). Besides, there has been the conversion of different

LULCC: Land use and land cover change.

classes of land use and land cover classes with different rates and magnitudes.

# LAND USE AND LAND COVER CLASSIFICATION

Land use/cover classification is the process of

mapping that is based on either visual or computer aided analysis to categorize all land cover features by their relative spectral patterns or unique similarities (Foody, 2002). Many classification systems are being used throughout the world including the world land use classification, the Canada land inventory and land use classification, the second land use survey of

Britain classification and Canadian land use classification (Scace, 1981). Even though there is not an internationally accepted format, most land use and cover studies especially in Ghana appears to be modelled based on the classification scheme of Anderson et al. (1976) (Table 2).

The application of remote sensing (RS) and

geographic information system (GIS) over the years has greatly enhanced image processing and classification for the production of thematic maps. It provides a map-like representation of the earth's surface that is spatially continuous and highly consistent, as well as available at a range of spatial and temporal scales (Foody, 2002). As a result, research on land use and land cover have demonstrated the full functionality of RS and GIS in (i) classifying past and present land uses (Boakye et al., 2008), (ii) predicting future changes (Amoah et al., 2012), (iii) evaluating the magnitude and rate at which these changes are occurring (Peprah, 2015), and (iv) spatially characterizing the patterns of change, pinpointing locations at risk (Yorke and Margai, 2012). This is made possible through the use of remote sensing imageries such as Landsat images (MSS,TM, ETM, ETM<sup>+</sup>), Systeme Probatoire D'observation de la Terre-High Resolution Visible Image (SPOT-HRV), IKONOS, Moderate-resolution Imaging Spectroradiometer (MODIS). Sentinel, QUICKbird, Advanced Very High Resolution Radiometer-National Oceanic and Atmospheric Administration (AVHRR-NOAA), Light Detection and Ranging (RADAR), GOES, ASTER, Advanced Land Observation Satellites (ALOS), European Remote Sensing Satellite (ERS-1&2), Japanese Earth Resources Satellite (JERS), Meteosat, Scanning Multi-Channel Radiometer(SMMR), microwave Special Sensor Microwave/Imager (SSM/I), etc. Among these imageries LandSat, ALOS, AVHRR-NOAA, SPOT and ASTER have been identified for land cover/land use and vegetation studies. However, review of land cover studies in Ghana shows most researchers prefers LandSat imageries (Braimoh and Vlek, 2004; Yeboah et al., 2017; Aduah et al., 2015; Boakye et al., 2008) due to the uniqueness of the dataset as the only long-term digital archive with a medium spatial resolution and relatively consistent spectral and radiometric resolution (Yang et al., 2000). It is also easily accessible and can be obtained at low cost.

Images are classified using either the supervised or unsupervised classification technique or sometimes both. The unsupervised classification uses cluster algorithms to automatically classify an image into several spectral classes based on statistical information within the image. The Cluster algorithms iteratively partition the image spectrally by determining statistical groups based on the numerical information (DN values) present in the image. However, supervised classification aims at allocating features based on their spectral peculiarity to a set of predefined classes. This method requires familiarity with the study area through field work, aerial photographs, conventional maps or google earth (Chuvieco and Huete, 2010; Jensen, 2005). Supervised classification systems can be grouped as either parametric or non-parametric methods. The parametric methods include maximum likelihood classification (MLC) (Campbell, 2002), fuzzyset classifiers (Stavrakoudis et al., 2011), sub-pixel classifiers, spectral mixture analysis (Nichol et al., 2010)

and object-oriented classifiers (Platt and Rapoza, 2008). The non-parametric methods include artificial neural networks (ANN) (Laurin et al., 2013; Atkinson et al., 2000), decision tree and support vector machines (Huang et al., 2002). However, available literature indicate that the statistically-based MLC algorithm classification is most preferred and used very often (Yeboah et al., 2017; Forkuo and Adubofour, 2012; Boakye et al., 2008; Kusimi, 2008a).

To assess the correctness of the classification, accuracy assessment is essentially performed in land use and land cover classification (Foody, 2002). Campbell (2002) defined accuracy in thematic mapping from remotely sensed data as the degree of 'correctness' of a map or classification. A map may be considered accurate if it provides an unbiased representation of the region it portrays. In other words, classification accuracy is the degree to which the derived image agrees with the reality or conforms to the truth (Smits et al., 1999). There are many methods of accuracy assessment in literature but the most widely used is the Error (Confusion) matrix though few challenges have been pointed out by Foody (2002). The confusion matrix provides a basic information of the proportion correctly classified (PCC). It may be useful in refining estimates of the areal extent of classes and also enhance the value of classification for the user (Foody, 2002). It also furnishes the analyst with errors of omission and commission as well as overall, user and producer accuracy (Lillesand and Kiefer, 1999). Most of the literatures reviewed in this study recorded an overall accuracy of 75% and above signifying strong agreement of the classified image and the reality (Yeboah et al., 2017; Peprah, 2015; Adjei et al., 2014; Forkuo and Adubofour, 2012).

An important tool in monitoring land use and land cover change is the change detection (Mertens and Lambin, 2000). Land use and land cover change detection is the process of identifying differences in the state of land features or phenomenon by mapping it at different times over a period (Coppin et al., 2004; IGBP/IHDP, 1993). It involves the use of multi-temporal datasets to identify areas of change between specific dates of imaging. Copping et al. (2004) categorized remote sensing techniques used for change detection as algebraic, transformation. classification and visual techniques. Algebraic based technique include normalized difference vegetation index (NDVI) differencing, image differencing, image regression and change vector analysis (CVA), the transformation method includes multidate Principal Component Analysis (PCA), Chi-square transformations and Kauth-Thomas (KT); the classification methods consist of post-classification comparison (PCC), multi-date classification, spectral-temporal combined analysis while visual analysis techniques is primarily based on the visual interpretation of aerial photographs and high resolution images. Algebraic and transformation methods are suitable for detecting continuous changes,

**Table 2.** Land use/cover classification scheme (Anderson et al., 1976).

Land cover	Description
Water	Water courses (streams, rivers), ponds/flooded, lakes, reservoir
Farms/Shrubs	Short tree species and non-tree, Vegetation such as herbs, grasses and farms, commercial and horticulture crops
Evergreen (deep) forest	Tall trees including indigenous species and mature rubber located mostly in forest reserves and plantation farms
Secondary (Open) forest	Degraded/re-growth forest and tree crops and rubber with open canopy
Settlement	Urban areas, Villages, Paved/Unpaved roads, bare land, car parks, playing fields
Mining areas	Areas where open cast/surface Mining has taken place and mining infrastructures

while classification methods are effective for categorical changes (Abuelgasim et al., 1999), but depend on the accurate geometric registration and classification of individual images. Continuous changes mean changes in the concentration or amount of an attribute (e.g. biomass and the leaf area index of a forest), while categorical changes are the conversion of one land cover type to another (e.g. forest to urban area). The reviewed literature indicates that the classification method. specifically the post-classification comparison is commonly used in the land use/cover change analysis, perhaps because of its effectiveness in categorical changes (Aduah et al., 2015; Kumi-Boateng et al., 2012), However, a good change detection method should indicate the area and rate of change, spatial distribution of changed features, change trajectories of cover types and accuracy assessment of change detection results (Inca, 2009). Change detection has numerous advantages in land use planning. Amongst them includes (i) the provision of the basis for coordinated policies and strategies to guide development at the local level and within the framework of implementing short-term actions, (ii) the revelation of the spatial pattern of development in the area whether negative or positive and thereby helping to identify areas where a particular type of change should be encouraged or discouraged (Lamber et al., 2001).

# DRIVING FORCES OF LAND USE AND LAND COVER CHANGES

Land use and land cover changes do not occur in vacuum. It is the resultant effect of human activities within the natural environment. Thence, land use/cover changes are determined by complex interactions of environmental and socioeconomic factors (Kelarestaghi and Jeloudar, 2011). The environmental factors include climate, geomorphology, soil and geology. According to IGBP (1993), possible socioeconomic forces behind land use/cover changes can be grouped into six namely population, level of affluence, technology, political structures, attitudes and values of the people. They further argue that land cover modification is mostly driven by human influence rather than natural changes (Ayivor and Gordon, 2012). This is supported by Benneh and Agyepong (1990) that population increase, development policies, urbanization and agriculture contributes greatly to land cover change. Again, some researchers within the country have shown that the rate of land cover changes are the direct results of population, urbanization and agriculture (Appiah et al., 2014; Boakye et al., 2008; Braimoh and Vlek, 2005) which are regional in nature as events in one location impact on land use in other locations (McCusker and Carr, 2006; DeHart and Soule,

2000). However, Lambin et al. (2001) opine that the utilization of new lands was created by local as well as national markets and policies. Therefore, the driving forces are not only regional or global in scale, but also local (Lambin, 2001) in that actions at the local level directly affect land use/cover. Of course the combined application of the various land use theories such as Malthusian and Boserupian that relate land use to population growth, the Ricardian paradigm that links land use to intrinsic land quality, and the Von Thu"nen paradigm that associates land use to location of land parcels (Mortimore, 1993) indicates that the driving forces are not only regional but also local. Hence, it is imperative for land use/cover researchers to dig deep down to the local level to identify specific factors influencing land use/cover change, be it global, regional or local.

#### SEDIMENT YIELD OF RIVER BASINS

Sediment yield and loading of river basins present important measure of the hydrology of the drainage basin and the erosion processes (Walling, 1999). Sediments are particles that can be transported by a fluid flow and deposited as a layer of solid particles on the bed of a body of water. Sediment yield of a catchment is the amount of sediment load passing through the

outlet of a drainage basin within a specified period of time (Jain et al., 2010; Verstraeten and Poesen, 2001). It involves bed load and suspended load expressed in terms of mass or volume per unit of time. Bed load sediments are those that are transported by saltation and traction e.g. gravels and cobbles whilst suspended load is sediment in suspension by the upward components of turbulent currents (Akrasi, 2011; Nagle, 2000) e.g. silt, clay, and sand. The amount of sediment transported downstream depends on the rate and magnitude of erosion and transporting capacity of the flowing medium, erodibility, rainfall erosivity, soil catchment topography, size and vegetative cover (Ndulue et al., 2015; Pelletier, 2012). Soil erodibility is defined by Hudson (1995) as the soil's susceptibility to erosion which varies with the soil texture, aggregate stability and shear strength apart from soil infiltrability and organic in addition to chemical content. The rainfall erosivity also defines the potential ability of rain to cause erosion. It is based on the kinetic energy and momentum of the runoff. Therefore, the erosivity index of the storm is a function of rain droplet distribution, frequency, intensity and velocity. Oduro-Afriyie (1996) used the Fournier index to estimate the rainfall erosivity indices for stations in Ghana. His results showed that the erosivity index, c for Ghana ranges between 24.5 mm in Sunyani and 180.9 mm in Axim. Small flows carry small sediment loads and are essentially ineffective in scour and deposition.

Topographic features that influence erosion are slope; its size and length as well as shape of a watershed and aspect of a mountain. The amount of erosion on an arable land is influenced by the steepness, length and curvature. Thus, the steeper and longer the slope, the more the erosion (Amegashie et al., 2011). Vegetative cover serves as the protective layer or buffer between the atmosphere and the soil. It interferes with the amount of rain drops reaching the soil surface. The vegetative cover depending on the canopy will protect the soil from the erosive activity of rainfall that is very high (Akrasi, 2008).

#### SEDIMENT YIELD ASSESSMENT AND MODELING

Soil erosion in river basins continues to be a serious problem in the world (Eswaran et al., 2001). Accurate determination of suspended sediment loads and its associated fluxes in rivers is of great importance for water resources development and management.

There are two approaches for determining the sediment loads in rivers; direct (field) measurement and modeling (physical and empirical). Field measurement methods usually include measurement of suspended sediment load and discharges (Kusimi, 2008b; Akrasi, 2005; Amisigo and Akrasi, 1997), measurement of total eroded sediments and deposited sediment in small catchments and measurement of sediment volumes in ponds, lakes or reservoirs (Amegashie et al., 2011; Adwubi et al.,

2009). Measurement of suspended sediment concentration involves sampling and laboratory analysis. Four main types of suspended samplers are available: integrating samplers, instantaneous samplers, pumping samplers and sedimentation traps. The preferred one is the integrating samplers. However, in the absence of depth integrated sampler some researchers such as Akrasi and Ansa-Asare (2008) and Kusimi et al. (2014) used the dipping method and applied the necessary correction according to Rooseboom and Annandale (1981) and Demmak (1976). The sampled water was taken to laboratory to determine the suspended sediment concentration through either the evaporation or filtration method. For high concentrations of sediment, the evaporation method is better whilst the filtration method works better for low concentrations of the water-sediment mixture (Ayibotele and Tuffour-Darko, 1979). Another possibility is to make measurement with a field turbidity meter that has been calibrated against natural samples from the site where its being used (Mawuli and Amisigo 2017; Minella et al., 2008). The suspended sediment concentration obtained can be used to compute for the sediment load in tons per day as well as the specific sediment yield (Akrasi, 2008; Kusimi et al., 2014)

As a result of the difficulties associated with obtaining continuous records of concentration through the direct method due to cost, remoteness of site, number of sampling and technical difficulties (Edwards and Glyssen, 1999) water researchers have resorted to the use of empirical models to estimate the suspended loads in rivers that have no direct measurement (Akrasi, 2011; Akrasi and Ansa-Asare, 2008; Syvitski and Milliman, 2007; Amisigo and Akrasi, 1997). These include the erosion rate method, catchment based method, rating curve method and regression method. For instance, in 1974, Ayibotele and Tuffour-Darko established sediment rating curves for suspended and bedloads for the Densu River at Manhyia, Amisigo and Akrasi (2000) also developed sediment yield prediction model for southwestern river basins in Ghana, Akrasi (2005) developed the same for the Volta basin system, while Akrasi and Ansa-Asare (2008) developed prediction model for Pra river basin using runoff and catchment area. Later, Akrasi (2011) developed simple empirical models using multiple regression to predict suspended sediment yield within the south-western and coastal river basis systems in Ghana. The models relate the sediment yield to the catchment area and simple climatological indices such as rainfall and runoff. However, sometimes the results obtained from the curve may be problematic since storm flow hydrographs usually, but not always, are characterized by higher suspended sediment concentrations during the rising limb than the falling limb. For instance, Kusimi (2008b) noticed from his study in the Densu river basin that even during low flows, sediment concentration remains relatively high.

Besides, there are various empirical models to estimate

the sediment yield of catchment such as the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978), Modified Universal Soil Loss Equation (MUSLE) (Blaszczynski, 2003) and the Revised Universal Soil Loss Equation (RUSLE) (Renard et al., 1997). The USLE/RUSLE is a field scale model and cannot be used to estimate the sediment yield directly. This is because it does not account for sediment deposition along the travelling path. To account for this Sediment Delivery Ratio (SDR) is incorporated to estimate the total sediment transported to the basin's outlet (Jain and Kothyari, 2000). However, USLE/RUSLE only predict the amount of soil loss through the sheet and rill erosions but not from gully, channel or bank erosion which may lead to underestimation. Notwithstanding, the RUSLE and its integration with GIS and remote sensing has been widely used by many researchers to display the spatial distribution of soil erosion and estimate the annual soil loss of a catchment with good results (Avalew, 2014: Kayet et al., 2018). The uncertainties that normally stem from the availability of long-term reliable data for soil erosion modelling are not unique to RUSLE application. The model is relatively simple, easy to parameterize and requires less data to operate with.

There are also physically-based models developed for hydrologic prediction and for understanding hydrologic processes which are very useful in environmental management. Particular models developed to explore the impact of land use change on hydrological processes includes Soil and Water Assessment Tool (SWAT) (Arnold et al., 1998), Water Evaluation Prediction Project (WEPP) (Nearing et al., 1989), European Soil Erosion Model (EUROSEM) (Morgan et al., 1998), Areal Nonpoint Source Watershed Environment Response Simulation (ANSWERS) (Beasley et al., 1980), Chemicals, Runoff and Erosion from Agricultural Management Systems (CREAMS) (Kinsel, 1980), Systeme Hydrologique Europian-TRANsport (SHETRAN) (Ewen et al., 2000), Kinematic Runoff and Erosion model (KINEROS) (Woolhiser et al., 1990), etc. These are event based models, continuous, spatially and temporally distributed at catchment scale. However, these models require huge amount of data inputs, and many calibration parameters, that are characterized by complex laboratory analyses or difficult and expensive field data collection (Silva et al., 2010). Hence, their application in developing countries where physical sediment data are virtually non-existent is highly limited.

#### **SEDIMENT YIELD STUDIES IN GHANA**

Even though sediment yield measurement in Ghana is deficient due to high cost and technical challenges, a number of studies have been conducted. Literature shows that between 1974 and 1976, Water Resources Research Institute (WRRI) measured bed load at eight

different gauging stations on some of the large rivers (basin >2000 km<sup>2</sup>) in southern Ghana (Ayibotele and Tuffour-Darko, 1979). Also, sediment loads of rivers in the south-western river basin systems of Ghana were measured (Amisigo and Akrasi, 2000). Table 3 gives an overview of current collected sediment yield data in Ghana and their sources. It must be noted from Table 3 that the sediment yield measurement from gauging stations (GS) are generally suspended load and do not include the bed load. This perhaps explains the differences between the sediment yield derived from reservoir sedimentation rate and gauging stations. Nonetheless, the difference may also be attributed to specific catchment characteristics and environmental conditions. For example, sediment observation from reservoirs are mainly for small catchment (<5 km<sup>2</sup>), while that from gauging stations are for relatively larger catchment (>100 km<sup>2</sup>). It shows small catchment generate more sediment because it has steeper gradient. less storage capacity, relatively shorter travel distance and less time for entrapment, and greater response to flood (Milliman et al., 1999).

Available literature also indicate that water researchers have developed predictive models to estimate sediment yield for rivers where no measurement is conducted. For example, Akrasi developed simple predictive tool from measured sediment data to estimate the total suspended sediment input to the Volta Lake. His results showed annual suspended sediment input of about 52 tkm<sup>-2</sup>year<sup>-1</sup> from the catchment surface (Akrasi, 2005). Also, Akrasi and Ansa-Asare used collected data within the Pra basin to develop simple empirical model to predict specific suspended sediment yield and nutrient export coefficients within the Pra basin. The sediment yield of Pra basin was estimated to be 50.8 tkm<sup>-2</sup>year<sup>-1</sup> (Akrasi and Ansa-Asare, 2008). Akrasi (2011) used measured suspended sediment transport for 21 monitoring stations in southern Ghana to develop simple predictive models for catchment where no measurement had been undertaken. The model results showed that the sediment yield of the southwestern and coastal basins ranged between 11 and 50 tkm<sup>-2</sup>year<sup>-1</sup> (Akrasi, 2011). The model indicated that runoff and catchment areas account for a large proportion of the variance of the suspended sediment yield.

#### SEDIMENT YIELD AND LAND USE/COVER CHANGE

Land use and cover features plays significant role in the erosion and sedimentation process of a catchment. They control the intensity of the rain drops reaching the soil surface causing erosion, and the frequency of the overland flow and sediment deposition (Mitchel, 1990; Bryan and Campbell, 1986). Hence, some land use and vegetative types create favorable conditions for runoff and sediment loss than others (Nunes et al., 2011). For instance, conversion of agricultural, forest, grass, and

<sup>&#</sup>x27;R' indicates that the sediment yield value was obtained from bathymetric surveys in a reservoir. 'GS' indicates that the value was obtained from measurements at a gauging station.

wetlands to urban areas usually comes with increase in impervious surface, which alter the natural hydrologic conditions such as runoff and sedimentation processes within a watershed. It therefore means that the sediment yield of a basin becomes more sensitive to variations in rainfall intensity and topography as the vegetative cover decreases from forest cover through agricultural crops to rangeland (Vanmaercke et al., 2014; Gellis et al., 2006; Trimble, 1995; Dunne, 1979; Wilson, 1973).

Rivers where sediment yield have both increased and decreased in recent decade resulting from changes in land use have been reported by several researchers in Africa and beyond (Kusimi, 2008b). Asante-Sasu (2016) showed that two years after the construction of Bui dam in Ghana, the gross sediment yield of the reservoir had increase by 41.5% over the designed figure resulting from land use activities. Ngo et al. (2015) concluded that the increase of agricultural land, expansion of urban area and the removal of forest land dramatically increased runoff and sediment of Da River Basin of Hoa Binh province. Again, Huang and Lo (2015) applied SWAT model to assess the impact of land use change on soil and water losses from Yang Ming Shan National Park in Northern Taiwan.

Their results showed that 6.9% decrease in forest and 9.5% increase in agricultural land caused sediment yield increase of 0.25 tha-1. Thus, Land use change has generally been accepted as influencing factor contributing to the variation in sediment yield of river basins (Ngo et al., 2015; Tang et al., 2005; Dunne, 1979; Douglas, 1967). However, the evidence for the impact of changing land use on the sediment yield of rivers is still less clear. The empirical relation linking sediment yield to land use features remains unclear. Developed empirical models for the estimation and prediction of sediment yield in river basins in Ghana do not reflect clearly the influence of changes in land use on the sediment yield. Rather, they relate catchment sediment yield to climatological indices: rainfall and runoff, and catchment area only (Amegashie et al., 2011; Akrasi and Ansa-Asare, 2008; Akrasi, 2005). Hence, the contention that land use is the dominant factor to sediment yield of river basins (Kusimi, 2008b; Walling, 1999) and that the influence of other factors becomes more pronounce in a changing land use has been cataloged thoroughly in literatures but without supporting data. Their results and models relate sediment yield to rainfall, runoff and catchment size more than vegetative cover (Amegashie et al., 2011; Akrasi, 2005).

#### **CONCLUSION**

Sediment yield of river basins poses great threat to the available water resources. It is generally accepted that sediment yield of a basin is influenced by the effect of land use/cover, rainfall and catchment geomorphology. Various land uses and sediment yield studies discuss the sensitivity of catchment sediment yield to land use change. However, the relative importance of land use/cover type in explaining the spatial variation in sediment yield is less clear-cut. Existing sediment studies and regression model results especially in Ghana relate sediment yield of studied catchment to rainfall, runoff and catchment morphology without exploring empirical evidence of land use impact. Though the observed variations in sediment yield have been strongly attributed to land use/cover changes, the results do not show strong influence of cover types on sediment yield. For sustainable water resources management, it is important to empirically explore the link between land use change and the sediment yield of river basins. The study also recommends the use of the RUSLE model to display the spatial distribution of soil erosion for data-deficient basins since it does not require huge amount of data for calibration and validation.

# Intra- household food allocation among adolescents in coffee farming households in Jimma Zone, South west Ethiopia

#### Getu Gizaw Haile\* and Kalkidane Hassen Abate

Department of Population and Family Health, Faculty of Public Health, Jimma University, Jimma, Ethiopia.

Received 6 June, 2018; Accepted 21 September, 2018

There are wide ranges of factors that determine individual food insecurity within households. In cash crop area products are for market rather than for agricultural households that can cause food accessibility to a severe challenge. There is, however, a dearth of information about the food security status of adolescent living inside coffee farming households. The aim of this study is to investigate the prevalence of adolescent food insecurity and determine its factors among coffee producing districts in Jimma Zone, South west Ethiopia. Community based cross-sectional study was employed in coffee producing district in Jimma zone, from April-May 2016. A total of 550 households having adolescents were included. Data were entered into EpiData and the analyses were made by SPSS version 20. Bivariate and multivariable logistic regression was done and p-value < 0.05 considered as a cut-off point to determine statistical significance. Sixty percent of adolescents (60%) were found to be food insecure. Female adolescents [AOR=2.18, 95%CI (1.4-3.48)], household food insecurity [AOR=9.4, 95%CI (5.49-16.19)], male of household heads [AOR=2.77, 95%CI (1.44-5.33)], high dependency ratio [AOR=2.53, 95%CI (1.447-4.446)], not formally educated household head [AOR=4.925, 95%CI (2.636-9.201)] and have no own land for farm [AOR=2.484, 95%Cl (1.24-4.96)] were positively independent predictors of adolescent food insecurity. This study highlighted the problem of food insecurity in coffee producing farmers. Sex of adolescent, dependency ratio, sex of household head, household heads' educational status, food security status of household and farm land owner ship are predictors of adolescent food insecurity. This pushes us to advance direct nutrition interventions focusing on adolescents to endorse catch-up growth and break the intergenerational cycle of malnutrition.

**Key words:** Adolescent, food insecurity, coffee farmer.

#### INTRODUCTION

FAO (2009) says food security exists when all everybody has physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs and

food preferences for an active and healthy life (FAO, 2009) all the time. Food security has four pillars: availability, access, utilization and stability. Availability (all

household members get reliable and consistent food), access (economic aspect of getting food), utilization (it is dietary intake and our body physiologic condition to absorb nutrient and food interaction to be absorbed) and finally, stability (FAO, 2009; US, 2010). FAO (2009) explains household food security as the use of food security concept to the household level, with individuals within households as the focus of concern (FAO, 2009). The interests of adolescent are not always clearly advocated in food security programs but as Feighery et al. (2011) affirm adolescents should be viewed as primary part of the solution to food security (Feighery et al., 2011) and their particular health needs (WHO, 2017). World populations quickly grow particularly in the developing world on condition that food security is challenging. The United Nations in 2017 estimate that by 2050 world populations will increase nearly to 2.5 billion people, among the greater part of this enlarge happening in the growing world. Moreover a lot of this growth will be along with adolescents, who will like compose half of the 2050 population. Because of these demographic transitions, adolescents are tremendously vulnerable to food scarcity. Moreover, current challenge of increasing food prices and crop loss from climate change weather patterns can make worse this vulnerability. The problem is much palpable in Ethiopia, which currently has the uppermost share of youth population at 21.8% for these reasons, they should focus on the overall youth group to address the developmental challenge associated with long term consequence of food insecurity (Lederer, 2017).

Though, there is a small number of studies that look at food security from adolescents' point of view (Brooks et al., 2013). Household Food Insecurity Access Scale (HFIAS) is one method used to measure food scarcity at family level; it was used within two recent surveys in Ethiopia (Ethiopian Health and Nutrition Research Institute, 2009), and different studies in developing courtiers show that these qualitative self-reports give valid indicators of food insecurity at individual level (Frongillo et al., 2006; Belachew et al., 2013; Belachew et al., 2012; Webb et al., 2006; Belachew et al., 2011).

Currently, there has been mounting conversation in coffee industry on the determinant of food insecurity in coffee cultivating population. Small-scale producers are expected to provide 70% of the world's coffee supply (Eakin et al., 2009). The remote countryside areas where the world's most excellent coffee is grown are exposed to several food insecurity threat factors (CFS, 2012). This is not common to one exacting area or a division of the population. Many reasons hinder smallholders' elasticity for making adjustments toward more productive or money-making crops, making to have insufficient cash to buy food; lack of time and/or land to contribute to cultivation of food crops (Caswell et al., 2012).

It is increasingly being recognized that one of the strategies used to reduce poverty and hunger is improving food security. Despite the well-known

development in financial growth and welfare enhancement in developing countries over the recent years, food security has not been achieved in most developing countries. Especially, food insecurity continues to form a deep-rooted problem in several sub-Saharan African (SSA) countries. FAO (2014)"s report indicates that the number of undernourished people in Africa is still high at 226.7 million (FAO, 2014). Even now, countries in the Horn of African are snowed under sensitive food security crises, making the problem of food security an issue of great concern to governments and the international community.

Even if it is clear that the household food insecurity condition represents the occurrence of individuals within the household, research – first from Asia – shows that this often is not true (Haddad et al., 1996). Different research centers on within-household favoritism against young children and women as some data show that young children are favored than adults in terms of food security (Leonard, 1991; Messer, 1997). There are works connected to food insecurity at the household level in reference to adolescents' food insecurity. This is particular true for individuals in sub-Saharan Africa (Haddad et al., 1996). Issues concerning adolescent and food insecurity are especially few in cash crop areas.

Adolescence is a challenging period for one's path of life and one in which individuals are expected to make a chain of life span change into adulthood. Nutritional status of the adolescents can affect those key transitions. Food shortage can cause nutritional and health related problem in their later life span (Kuruvilla et al., 2016). The aim of the study is to have an understanding of the intra- household food insecurity in Jimma zone coffee producing districts by investigating adolescent food insecurity and its associated factor in Gomma, Manna and Limu- kosa coffee producing districts. Ethiopia remains the top producer of coffee in Africa and is the fifth largest coffee producer in the world. Our country is the origin of Coffee Arabica and frequently produces this in array. Coffee has soci- economic significance to the country. 95% of the coffee produced is organic as most of them are grown using traditional method without pesticides and fertilizers. These factors give Ethiopia a comparative advantage in the international specialty coffee market. Despite all these positive factors, the country contributes only 4.2, two percent of the total world coffee production (Francom and Counselor 2015; Tefera and Tefera, 2014), and food insecurity is a major challenge.

#### Rationale of the study

Currently, we have an extraordinary chance to advance the health of adolescents and answer more effectively to their specific requests. The global strategy of health of women, children and adolescents (2016-2030) identifies adolescents as critical in attaining SDGs (Kuruvilla et al. 2016). Adolescents constitute 16% of the world's population. And they account for 6% of the world's global burden of disease and injury. The recent very rapid reductions in mortality among infants and young children have not been observed among adolescents. Investments in adolescent health will bring a triple dividend of health benefits (for adolescents now, in the future and next generation) (WHO, 2017).

Ethiopia is one of the least developed countries in the world according to all measures of poverty. Even though the country has made improvement in economic growth over recent decade, food insecurity is marked. Previous studies have taken only the views of the household head into reflection in classifying food insecurity status of the household. By so doing, the potential of discrepancy experiences of food insecurity by individual household members was unnoticed. To date, however, due to limited information regarding food insecurity for adolescents within a household in coffee producing districts in Jimma zone, intra-household differences in food insecurity among adolescent have not been examined. This paper will address this research gap.

#### **METHODLOGY**

#### Study area and design

The study was conducted in Jimma Zone, Southwestern Ethiopia at community level. The study is a cross sectional design. Jimma Zone is known for organic Coffee Arabica production. The zone has consistent good rain (Lemessa, 2000); however, the climate of Ethiopia has changed. Ethiopia has been having increased temperature of about 0.3°C per decade (from the 1950s), and in some areas low rainfall (Farming, 2017). This can threaten the food security of the zone.

#### Sample size calculation and sampling technique

Single population proportion formula was used to determine sample size with the following assumptions: prevalence of adolescents' food insecurity of 20.5% in Jimma Zone (Belachew et al., 2011); 550 study participants were proportionally allocated to each district; multistage sampling technique was used to get information. The inclusion criteria include: being a permanent registered farmer residing in the districts; at least one that has witnessed the latest harvest season with their adolescents.

#### Data collection and procedures

To collect the data an organized questionnaire was used. For households' characteristics, mothers were our primary choice instead of fathers. Pretest was done on 5% nearby districts and all possible amendment was made. The final data were collected by trained nurses, while supervision was made by trained nutritionists. Ethical clearance was obtained from the Review Board of Jimma University, College of Health Sciences and local concerned boys.

#### Measurements and analysis

Adolescent food insecurity was calculated with a customized

version of the household food security scales by choosing the things that relate to their individual practices (Frongillo et al., 2006; Belachew et al., 2011, 2013, 2012; Webb et al., 2006). They were asked of their last one month's own experience. Rarely, sometimes and often responses were coded as one and "never" responses were coded as zero; the responses were summed to produce an index of adolescent food insecurity and were further dichotomized as "food secure" for a score equal to zero "food insecure" and a score greater than zero. Household Food Insecurity Access Scale (HFIAS) version 3 was used to measure food insecurity, a tool that has been developed by FAO and FANTA and validated for use in several developing countries to assess household food security status including Ethiopia (Coates et al., 2007).

Data coding and editing was done manually; entry was done using Epi Data 3.1 version and then exported to SPSS version 20 for analysis. Data were checked for its distribution by P-P plot for all numerical variables and also multi-collinearity was checked. Frequencies and percentages of variables were produced and presented in table and graph; wealth index was generated using principal components analysis. Bivariate and multivariable logistic regression analyses were done to get this association: a p- value <0.25 and p-values < 0.05 respectively were the cut offs.

#### **RESULTS**

#### Adolescents' socio demographic characteristics

More than half (56.7%) of the adolescents were females while their mean age was 13.37(SD=: 2.448). Regarding their educational status, majority of them attend secondary school 383(69.6%) followed by primary school 110(20%). Only 223(40.5%) of them have access to food outside their homes (Table 1).

#### Socio-demographic characteristics of household

Of the 550 households 469(85.3%) were rural residents and 81(14.7%) were urban residents. Four hundred forty five (80.9%) households were headed by males. Majority of the respondents 496(90.2%) were married. Regarding religion more than two third (69.8%) of the respondents were Muslims followed by 144 (26.2%) orthodox. Most (72%) of the households were Oromo by ethnicity followed by Dawero 81(14.7%). The mean household size was 5.89 (SD±1.65); concerning households' dependency ratio, 168(30.5%), 200(36.4%) and 182(33.1%) had low, middle and high dependency ratio, respectively (Table 2).

Regarding their educational status 263 (47.8%), household heads have completed grade 1-8 followed by secondary education 164(29.8%); whereas most of spouses 262(47.6%) have completed grade 1-8. Concerning household wealth, 227(41.3%), 158(28.7%) and 165(30%) households have low, medium and high wealth index, respectively, while mean monthly expenditure on food was 1114.38 Birr (SD 641.8). More than two third (68.4%) husbands purchase food, whereas more than three quarter (76%) of households do not have access to savings and credit (Table 2).

Ever Had To Ask Outside The Home For Food.	Sometimes	14	2.5
	Often	0	0

#### Agricultural related characteristics

Majority 474(86.2%) of the households have their own land for farm. More than half (53.6%) don not use agricultural inputs and 58.4% do not use agricultural extension service (Table 3).

#### Prevalence of adolescent food insecurity

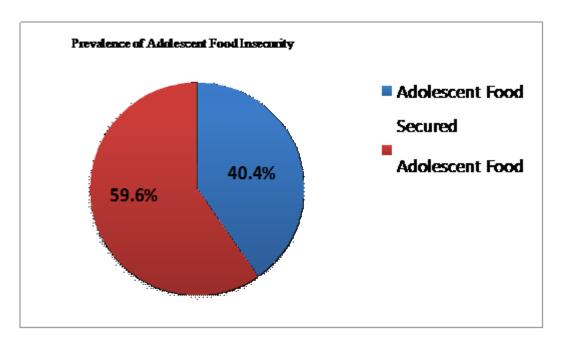

A high number of adolescents gave positive responses to reduction of meals (48.7%), 42.7% worry about food inaccessibility, 15.1% spend the whole day without food and 35.7% have never ask for food outside their homes (Table 4). In all the prevalence of adolescent food insecurity is 59.6% (Figure 1).

#### Prevalence of household food insecurity

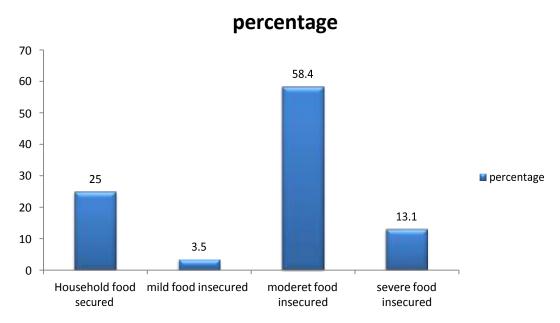

From all the pictures of HFIAS, the proportion of household food insecurity was 75%. From this, 19(3.5%), 321(58.4%) and 72(13.1%) were mildly, moderately and severely food insecure respectively (Figure 2).

#### Factors associated with adolescent food insecurity

Bivariate and multivariable logistic regression analysis was done using enter method to identify factors associated with adolescent food insecurity. On the Bivariate analysis, adolescent food insecurity had statistical association with 13 factors which had p<0.25.

**Figure 1**. prevalence of adolescent food security status in Mana,Gomma and Limu- kosa coffee producing Woredas in Jimma zone, south west Ethiopia 2016.

**Figure 2.** Prevalence of household food insecurity in Mana, Limu-kosa and Gomma coffee producing districts, Jimma zone, south west Ethiopia 2016.

Multivariable logistic regression analysis confirmed dependency ratio, sex of household head, household head educational status, land owner ship, sex of adolescent and household food security status as potential predictors of adolescent food insecurity (p<0.05) (Table 5).

By taking other variables constant female adolescents were 2 times more likely to be food insecure than male

[AOR=2.18, 95%CI (1.4-3.48)]. Adolescents living in a food insecure household were 9.4 times more likely to be food insecure than their counterparts [AOR=9.4, 95%CI (5.49-16.19)] and adolescent living in households without their own land for cultivating coffee were 2.5 times more likely to be food insecure than those living in households having their own land for coffee farm [AOR=2.484, 95%CI (1.24-4.96)] (Table 5). Adolescents living in female

headed households were almost 2.8 times more likely to be food insecure than those living in male headed household [AOR=2.77, 95%CI (1.44-5.33)]. Adolescents living in household heads not formally educated were almost 5 times more likely to be food insecure than those living in households whose heads have secondary school education [AOR=4.925, 95%CI (2.636-9.201)]. Adolescents living in household whose heads have primary school education were 3.4 times more likely to be food insecure than those living in households whose heads have secondary school education [AOR=3.44, 95%CI (2.09-5.67)]. Adolescents living in a household with high dependency ratio were 2.5 times more likely to be food insecure than those living in households with low dependency ratio [AOR=2.53, 95%CI (1.447-4.446)]. Adolescents living in a household with middle dependency ratio were 2 times more likely to be food insecure than those living in households with low dependency ratio [AOR=2.04, 95%CI (1.2-3.480] (Table 5).

#### **DISCUSSION**

This study revealed that more than half (59.6%) of the adolescents were food insecure which was higher compared to a research conducted in Jimma which was 20.5 and 48.4%, respectively (Belachew et al., 2011,

2012). The observed difference could be due to seasonal variation of food insecurity. This study was done in pre harvest (flowering) season of coffee which is more vulnerable to food insecurity. Female adolescents were more likely to be food insecure than their counterparts. This result is inconsistent with research conducted in Zimbabwe where there was no gender difference in adolescent food insecurity (Gundersen et al., 2007). In this study gender stratification might be due to the biased hoarding of food by elders and/ or males have more chance of getting food outside their home.

The findings do make sense in the socio-cultural context of Ethiopia, and definitely in many countries, where patriarchy is the dominant cultural model (Facio, 2013). This finding is best explained by other findings of the study, stating that only 28% females had access to food outside their homes compared to 56% of male adolescents who could access food outside their homes. The study showed majority (75%) households were food insecure calculated from full version of HFIAS tool. The adolescents living in a food insecure households were more likely to be food insecure than adolescents living in a food secure household. This finding is in line with the study conducted in Jimma zone (Belachew et al., 2012). This finding shows elders can give priority to younger children and in sever condition both can experience food insecurity.

In this study adolescents living in a household in

which the head has completed primary and secondary school were less likely to be food insecure compared to those adolescents whose households' head are not formally educated (Oluyole et al., 2009; Birhane et al., 2014; Gecho et al., 2014). The possible explanation is educated parents can use advanced technology. Adolescents living in a male headed household were 2.7 times more odds of food insecure than counterparts. It might be that most males that control financial assets like money spend it for other activity rather than food (Meinzen-et al., 2011). Adolescents who were members of households with high and middle dependency ratio were more likely to report food insecurity compared to those in low dependency ratio households. This study is similar to a study done in Jimma, Nigeria and USA (Belachew et al., 2012; Ojogho, 2010; Coleman-Jensen et al., 2013). This could mean that as the dependent age group size increases, there is larger number of people to be taken care of by the same source of income. Adolescents who are members of households without their own farm land were more likely to be food insecure than their counterparts. The reason is that households who rent land can pay the owner some portion of production from this plot.

#### Conclusion

Generally, it was found that there was high prevalence of adolescent and household food insecurity in the study area. Sex of adolescent, dependency ratio, sex of household head, educational status of household head, household food security status and farm land owner ship are predictors of adolescent food insecurity. There is need to improve direct nutrition specific interventions targeting adolescents. School feeding program should be an integral component of food security intervention to reduce intergenerational rotation of undernourishment. Multi-sectoral interventions approach should be improved to address multifaceted causes of food insecurity; gender equality and the status of women and girls through operative health information at ordinary level needs to be considered. Further research is required to seethe cyclic pattern of seasonal food insecurity in the study area using different methodological approach like longitudinal study.

#### **CONFLICT OF INTERESTS**

The authors have not declared any conflict of interests.

#### **ACKNOWLEDGMENTS**

Authors would like to express their thankfulness to respective data collectors, supervisors and study participants for their diligence and devotion in the

collecting and inputting high quality data used in the study.
